(54) Title: TISSUE ARRAY INSTRUMENT

(57) Abstract: Arrays of biological tissue can be created by removing cores from regions of interest in a series of donor blocks (15) of embedded tissues. The cores removed are placed in a regular array in a recipient block (15). This is typically done with two different punches, one for obtaining the cores of interest and the other for creating the receiving holes in the recipient block (15). The present invention comprises such a system including two separate z axes, one for each punch. Each punch has its own stylus and the axis of each punch is parallel to the axis of its drive. Alternatively, the invention is made by providing a single z axis, with a mechanism for automatically changing two or more punches in and out of a holder on the z axis.

TISSUE ARRAY INSTRUMENT**Field of the Invention**

Arrays of biological tissue can be created by removing cores from regions of interest in a series of donor blocks of embedded tissues. The cores removed are placed in a regular array in a recipient block. This is typically done with two different punches, one for obtaining the cores of interest and the other for creating the receiving holes in the recipient block. The present invention concerns a simplified and economical system and device for the automated creation of tissue arrays.

Background of the invention

Biological tissue arrays consist of regular arrays of cores of embedded biological tissue arranged in a sectionable block typically made of the same embedding material used originally for the tissue in the cores. The new blocks may be sectioned by traditional means (microtomes etc.) to create multiple nearly identical sections each containing dozens, hundreds or even over a thousand different tissue types. These sections may be used for histochemical and other assays. Any test performed on any one of these sections is effectively performed on hundreds of samples at once. The result is a tremendous saving in effort and time and some increase in the availability and precision of control samples. Tissue arrays have been constructed entirely manually (Battifora, H., "The Multitumor (sausage) tissue block: novel method for immunohistochemical antibody testing," Laboratory Investigation Vol. 55, pp. 244-248, 1986) and with the assistance of mechanical mechanisms (Kononen et al "Tissue microarrays for high-throughput molecular profiling of tumor specimens", Nature Medicine Vol.4 Number 7 July 1998 pp. 844-847) for a variety of biological applications.

A manual instrument has been described in US Patent 6,103,518 (Leighton) entitled "Instrument for constructing tissue arrays". The manual methods have largely been superseded by those aided by instruments due to the speed, precision and increased density of the latter. In these devices, two hollow needle-like punches are used. One, slightly smaller, is used to create a hole in a

recipient block, typically of paraffin or other embedding medium.

The other, the slight larger punch, is used to obtain a core sample from a donor block of embedded biological tissue of interest. The punches are sized such that the sample obtained from the donor block just fits in the hole created in the recipient block. Thus the sample is a snug fit in the recipient block and a precise array can be created.

The recipient block is held in an appropriate fixture during the entire process - although it may be removed and be alternated with one or more other recipient blocks to create more than one array from one set of donor blocks. Micrometer drives or other precision linear positioning means position the punches with respect to the recipient block or the recipient block with respect to the punches. It is clearly desirable that the donor punch reach exactly the same x,y position that the recipient punch reaches on the recipient block for a given setting of the micrometer drives. If it does not, the retrieved sample will not pass smoothly into the hole just created for it, but instead will be damaged or lost. It is further desirable that this motion be created reliably and inexpensively.

In Kononen et al it is taught to use slides and drive mechanisms to first move the recipient punch into a central position and, alternately, the donor punch. This mechanism is cumbersome, expensive, slow and prone to misalignment errors. The use of slides at an intermediate angle such as 45 degrees, as taught by Kononen et al is particularly problematic, as small errors in height positioning can lead to corresponding errors in lateral position and vice versa.

Leighton US patent 6,103,518 entitled "Instrument for constructing tissue arrays") teaches a turret or other means allowing two punches to share a single z axis slide or drive. This mechanism is appropriate for a simple, manually operated instrument, but may be awkward for an automated instrument in which all motions are driven by powered actuators (pneumatic, electric etc.). Special mechanisms must be machined and assembled, and standard components are not available.

While the above systems are operable, there remains a need for a system which can be fully automated yet has fewer robotic parts than the above-described systems.

Summary of the Invention

It is the purpose of the present invention to overcome the cumbersome quality and slow speed of the prior art and to provide a simple precise means of alternately positioning the two punches in any tissue array instrument. In addition, it is the purpose of the present invention to provide a means for constructing a robust automated instrument.

The invention comprises completely separating the two punches (donor and recipient), giving each their own stylet (unlike the above-described device) and each their own z-drive (unlike Leighton). The x and y drives that must be present to bring different areas of the donor and recipient blocks into position under the punches in any arrayer can be simply programmed with appropriate offset values to position the point of interest under either punch in turn as required.

Since this offset value is now used in the control, it may also be used for a further improvement: The positions of the tips of the two punches can be periodically measured automatically by sensors mounted on the same pallet as the donor and recipient blocks. Whenever their positions may have moved (perhaps due to encountering a more dense block or irregularity, or perhaps by being disturbed by an operator or foreign object, or simply being altered by virtue of a new punch being installed) then the new positions can be measured and automatically used to update the offset value. This novel combination of

a) sensing the tip positions with a sensor mounted on the block holding pallet with

b) two different z drives

allows a system to be constructed with standard components and to be robust in the face of environmental challenges and mechanical drift.

Each z drive moves its respective punch in line with the axis of the punch. Firstly, each drive can move its punch completely out of the way of the recipient and donor blocks, for example when the other punch is being used or when the x and or y drives are being used to move different points on the blocks under the punches or for observation. Secondly, each drive can move its punch to just contact or nearly contact the surface of a block,

for example for depositing a donor core into a recipient block. Thirdly, each drive can move its punch into the blocks, for example for obtaining and removing a blank core from a recipient block or a tissue core from a donor block.

Since each of the two drives can move its punch into and out of the way as well as to cause it to touch or penetrate the appropriate block, only two drives are required for two punches. In the co-pending application in which the present inventor is co-inventor, four drives are required, two for moving the two punches into and out of position, and two for moving the punches into and out of the blocks. In Leighton, manual operation is contemplated, but were the system to be automated, two drives would be required, but they would need to be of two different types, one for toggling the turret from one position to the other, and another for moving the turret up and down. This would result in greater costs, as two different types of drives would be required to be designed and manufactured for the two different types of motion. In the present invention, the two drives can be identical, leading to reduced costs and simplicity.

It is within the scope of this invention to use more than two punches, each with its own drive, for example to permit quick changes between different sizes of punches for different applications.

The rest of a system using this improvement may be similar to that already described in the prior art. For example, powered or manual micrometer drives or the like may be used to position the punching mechanism over the blocks or the blocks under the punching mechanism. A removable bridge may be used for supporting the donor blocks over the recipient blocks, or the donor blocks may be attached to the same pallet that holds the recipient blocks. The latter arrangement allows the same x and y drives and slides to be used for both donor and recipient blocks.

In a further development of the present invention, the present inventor realized that in all of the prior art it has been the conventional thinking that the two different punches should be held permanently in some part of the mechanism or drives. Apparently, it may have been thought that permanently holding the punches in respective holders was necessary in order to guarantee accuracy and correct alignment, or that primary goals of

operational simplicity and speed in a single, dedicated machine blinded those working in this art to the possibility of using a single set of x-y-z axes and then adding a mechanism for alternately placing first one and then the others of two or more punches into position on the working end of one of the axes.

The present inventor has now surprisingly discovered that the duplex robotics of the prior art are not required, and has developed a simple and precise means of forming tissue arrays by alternately positioning the two different punches in any tissue array instrument.

The invention comprises completely separating the two punches (donor and recipient), giving each their own stylet (unlike Kononen et al) and using a single z-drive (unlike the double z drive disclosed in the Leighton patent application) but not resorting to a cumbersome turret or slider means (as disclosed e.g. in Leighton US Patent 6,103,518 "Instrument for constructing tissue arrays"). The improvements over the prior art include using changeable punches that can automatically and alternately be held by a moving gripper and actuator.

The x, y and z drives that are present for general positioning in most laboratory robots can be simply programmed not only to bring the active punch to the appropriate position with respect to a donor or recipient block and to do the punching, but also to bring the punch holder to a magazine or storage area, to release one punch, and to acquire another.

The positions of the tips of the two punches can be periodically measured automatically by sensors mounted on the same pallet as the donor and recipient blocks. Whenever their positions may have moved (perhaps due to encountering a more dense block or irregularity, or perhaps by being disturbed by an operator or foreign object, or simply being altered by virtue of a new punch being installed) then the new positions can be measured and the measurement automatically used to update the offset value.

Sensing the tip positions with a sensor mounted on the block holding pallet allows a system to be constructed with standard components and to be robust in the face of environmental challenges and mechanical drift. The position sensing may be used to overcome any variation in tip position caused by alternately replacing the punches automatically.

Typically, the punches are stored in simple holders attached to the same substrate that holds the donor and recipient blocks and a complementary holder or gripping means is attached to a member or arm that can move in x, y and z with respect to said substrate. (Of course, there are various combinations of motion that are obvious to one skilled in the art, such as having the substrate fixed with respect to the laboratory frame of reference and the arm moving in x, y and z or the substrate moving in x and y and the arm moving only in z or the substrate moving in x and the arm moving in y and z etc. The reference to movement in the z axis should be understood as relative movement between punch and donor or recipient block.) The holder or gripping means can be switched between a gripping and releasing mode by the same computer or controller that is controlling the rest of the operations of the instrument, or the gripping and releasing may be entirely mechanical, activated by the approach and withdrawal motions of the gripper with respect to the holding location.

Once the appropriate punch is firmly held in the gripping means, the motion drive can move the punch to the appropriate position for punching holes in a recipient block, discharging waste to a waste receptacle, acquiring tissue from a donor block, or inserting tissue into a recipient block. A surface sensing device could either be permanently attached to the moving arm or could be an alternate tool that can be picked up when needed instead of one of the punches.

Since each of the two punches can be picked up and used by the same axis, only one x, y, z drive system is required. Compare Kononen et al, where six drives are required, two for moving the two punches into and out of position, one for moving the punches into and out of the blocks and two for x, y motions of the blocks. In Leighton (US patent 6,103,518 "Instrument for constructing tissue arrays"), manual operation is contemplated, but were the system to be automated, four drives would be required, and they would need to be of two different types, one for toggling the turret from one position to the other, and another for moving the turret up and down. This would result in greater costs, as two different types of drives would be required to be designed and manufactured for the two different types of motion.

In the present invention, a standard laboratory robot can be

used, leading to reduced costs and simplicity.

While two punches are employed in the above discussion for simplicity, it will be readily understood that it is easily within the scope of this invention to use more than two punches, each stored in a similar holder on the substrate, for example to permit quick changes between different sizes of punches for different applications. It is also possible to use the punch holder to hold a tool for moving blocks, a tool for labeling blocks, or other tools or devices.

The rest of the system may be similar to that already described in the prior art. For example, powered or manual micrometer drives or the like may be used to position the punching mechanism over the blocks or the blocks under the punching mechanism. A removable bridge may be used for supporting the donor blocks over the recipient blocks, or the donor blocks may be attached to the same pallet that holds the recipient blocks. The latter arrangement allows the same x and y drives and slides to be used for both donor and recipient blocks. Alternately, separate x, y systems could be used for the recipient blocks and the donor blocks. This is more complicated, but can permit faster operation for high-throughput systems.

BRIEF DESCRIPTION OF THE DRAWINGS

For a fuller understanding of the nature and objects of the present invention reference should be made by the following detailed description taken in with the accompanying drawings in which

Fig. 1 is an isometric semi-schematic drawing of the invention, seen from the operator's perspective; and

Fig. 2 is a longitudinal cross-section of one of the punch/stylet assemblies.

Fig. 3 is an enlarged view of one of the punches and its relationship to the sensors as shown in Fig. 1.

Fig. 4 is an isometric semi-schematic drawing of the punch-changing tissue array instrument.

Fig. 5 is a detailed view of a clamp-type gripping mechanism.

Fig. 6 is a detailed view of an orifice-type gripping mechanism.

DETAILED DESCRIPTION OF THE INVENTION

The present invention provides a means for constructing tissue arrays that is simple, fast and easy to automate. The improvements over the prior art are in a first aspect of the invention attributable to using separate z axes, one for each punch, and or that the duplex robotics of the prior art are not required, and has developed a simple and precise means of forming tissue arrays by alternately positioning the two different punches in any tissue array instrument. In a second embodiment of the invention, the simplification of automation is achieved by completely separating the two punches (donor and recipient), giving each their own stylet (unlike Kononen et al) and using a single or double z-drive, but not resorting to a cumbersome turret or slider means (as disclosed e.g. in Leighton US Patent 6,103,518 "Instrument for constructing tissue arrays"). The improvements over the prior art thus also include using changeable punches that can automatically and alternately be held by a moving gripper and actuator.

Additional novel features are discussed below.

Wadding or packing at the end of the stylets

Wadding or packing may be provided at the end of the stylets to seal the gap between the stylet and the punch to keep the core from being extruded along the stylet and damaged and/or lost.

In the prior art, the stylets are metal wires sliding in the metal punch tubes. This rather crude arrangement is functional but, depending on the tissue type, temperature and closeness of fit of the wire and the tube, some of the tissue can extrude between the wire and the tube, leading to unpredictable losses of tissue. In addition to the simple loss of the tissue, this causes the additional problem of a different volume of tissue beneath the stylet and arrays being constructed with non-uniform depths. This non-uniformity leads to a much reduced yield of useful sections that can be cut from the array block.

The present invention comprises the use of small pieces of wadding or packing at the tips of the stylets to prevent this extraneous extrusion. These pieces can preferably be elastomeric

material such as polyurethane, natural rubber or polyvinyl chloride or the like. They can be made to fit the punches exactly by using the punch as a tool to punch exactly the correct size disc from a sheet of the chosen material.

Force control of the stylet

A drive for one or both stylets can be designed to exert prescribed forces as well as moving to precise positions, to allow tamping of the cores for better grip by the punches and easier removal of the cores from the blocks.

The closest system of which the inventor is aware for automated tissue arrayers uses only positional control of the stylet. This has the disadvantage that the stylet can only be withdrawn entirely out of the way of the tissue or wax cores while they are being acquired or pushed down flush to the end of the punch to insert the tissue core in a recipient block. Although intermediate positions are possible in theory, they are not useful as the automated machine has no information on the exact length of the wax plug with which to calculate an appropriate intermediate position for the stylet. There are combinations of tissue type, wax type, temperature and punch geometry for which it has been a problem to reliably extract the core from the block. Although the punch may have cut out a core, it is not removed because it is still held at the bottom by the block and there is not enough friction along the sides of the punch to grip the core and break the connection to the block at the bottom.

The present invention includes controlling the force applied to the stylet such as by means of a pneumatic or hydraulic cylinder. This controlled force can be set high enough to push the core completely out of a punch into a tissue block or at an intermediate value for tamping the core just before it is withdrawn. The tamping compresses the core axially and thus expands it radially against the cylindrical walls of the punch. This increased radial force creates a stronger grip of the punch on the core and enables the punch to extract the core. This phenomenon is somewhat counter-intuitive as some users of earlier automated machines thought that the axial force would push the core completely out of the punch. Indeed it would push it out if large forces were used to force the stylet all the way to the end

of the punch tube. Earlier descriptions of automated machines teach simple cycles involving the stylet either being at one end of its full stroke or the other.

The controlled force may be exerted by any number of ways well known in the art, such as pneumatics, hydraulics, controlled current motors, feedback systems involving force sensors on any sort of actuator or combinations of springs and various mechanisms.

The invention will now be described in greater detail by reference to the embodiment illustrated in the figures.

In Fig. 1 punches 1 and 2 are held by arms 3 and 4 and are moved vertically by drives 5 and 6. Stylets 7 and 8 are provided, respectively, for each of the two punches. They are moved vertically with respect to the punches by actuators 9 and 10. Drives 11 and 12 are provided for the stylet actuators. A computer 13 controls all of the drives or actuators. A pallet 14 is moved in the x and y directions by actuators 17 and 18. The pallet holds recipient blocks 15, donor blocks 16, a waste receptacle 19 and sensors 20. The sensors 20 detect the stylets allow the computer to find the position of the punches with respect to the pallet. Other sensors, limit switches, encoders and feedback elements may be necessary but are not shown for clarity since their use is well known in the art. For this purpose, US Patent Nos. 6,103,518 and 6,136,592 are incorporated herein by reference.

Turning now to Fig 2, there is shown punch 21, a stylet 22 within the punch, a piece of wadding or packing 23 and a tissue or wax core 24.

Fig. 3 is an enlarged view of one of the punches of Fig. 1, and better shows the 2-way hydraulic or pneumatic actuator 9 in relation to the sensors 20.

Although there are many ways to construct a device within the contemplation of the inventor, one preferred embodiment is described here. Two punches, a recipient punch 1 and donor punch 2, are positioned, each on a separate electromechanically actuated slide 5,6. The respective stylets 7,8 are independently driven by

simple pneumatic cylinders 9,10. The pneumatic cylinders allow precise positioning of the stylets in either the fully up or fully down position, and also allow controlled forces at intermediate positions for tamping the cores, merely by adjusting the air pressure.

It would also be within the scope of the invention to use electromechanical actuators - with force sensors if necessary - instead of the pneumatic cylinders. Similarly, pneumatic or hydraulic cylinders could conceivably be used for positioning the punches.

Preferably, electromechanically driven slides position a pallet 14 in the x and y axes to allow precise positioning of a set of one or more recipient 15 and donor blocks 16 under the punches. Alternatively, the pallet may be circular and may be driven in a circular motion. All that is necessary is that precise, predictable repositioning of the donor and recipient blocks relative to the punches can be effectuated. All of the motions may be under electronic and computer control by any of many well know means - limit switches, sensors, position feedback, stepper and/or servo motors and the like.

A typical cycle consists of the desired recipient position being brought under the recipient punch by the x-y drives; the recipient punch being moved by its z drive to penetrate and remove a blank core, creating a pocket for later use; the recipient punch being brought (by the x-y drives) near a waste receptacle (which may be mounted on the same x-y pallet as the blocks) and the recipient stylet being moved to discharge the blank core into the waste receptacle; the desired position of a donor block being brought by the x-y drives under the donor punch; the donor punch being moved by its z drive to penetrate and remove a desired core of tissue; the previously created pocket in one of the recipient blocks being brought by the x-y drives under the donor punch; and finally the donor punch being brought in contact or nearly in contact with the recipient block by its z drive and then its stylet being moved to implant the tissue core in the pocket created in the recipient block. Next, the lateral position is incremented with drives X and or Y to the next position and the cycle is repeated.

It is within the scope of the invention that either the blocks or the punches can be moved in x, y and z directions relative to the laboratory frame of reference - only relative motion matters in this invention.

For example, instead of being rigidly attached to a fixed base or frame, either or both z-axis drives may be mounted on horizontal positioning drives to move them with respect to the fixed base and hence with respect to the pallet instead of moving the pallet with respect to the fixed base. Alternatively, the pallet could be moved in the x direction, for example and one or both drives in the y direction. Alternatively, a positioning system based on polar coordinates could be used, with one or the motions being rotational and the other a radial motion. In fact, for example the donor blocks could be mounted on a computer driven turntable and the recipient blocks on a different turntable, with the z drives moved linearly horizontally from one turntable to the other. This linear motion would also serve to select radial positions of interest on either turntable. Alternatively, one set of block could be on an x-y table and the other on a rotary table, or each on their own x-y table.

It can be seen that there are many combinations and permutations possible with advantages for different applications. The key element that all have in common is the use of at least two separate z drives.

Further, in order to increase the range or capacity of the unattended instrument, it is possible to further provide a magazine containing donor and/or recipient blocks, either fresh or punched, wherein the magazine is operatively associated with said instrument for providing blocks to said instrument and/or receiving blocks from said instrument.

In Fig. 4 there is illustrated a punch-changing tissue array instrument wherein punch 31 is held by arm 33 and moved vertically by drive 35. Coaxially inside the punch is stylet 37 moved by drive 41 for the stylet actuator and moved vertically relative to the punches by actuator 39. A computer 43 controls all of the drives or actuators. A pallet 44 is moved in the x and y directions by actuators 47 and 48. The pallet holds recipient

blocks 45, donor blocks 46, a waste receptacle 49 and a sensor 50.

The sensor allows the computer to find the position of the punches with respect to the pallet. Other sensors, limit switches, encoders and feedback elements may be employed but are not shown for clarity of the illustration, and since their use is well known in the art.

Fig. 5 shows a dual clamping mechanism as one possible type of gripping mechanism. Computer controlled solenoids 70, 73 are connected to clamping jaws 71, 74 via actuating arms 72, 75. The upper clamping jaw grips the stylet hub and is connected to the stylet drive, the lower clamping jaw grips the punch hub and is connected to the punch drive.

Fig. 6 shows an alternative dual gripping mechanism. Stylet gripper 80 has an orifice slightly larger than the stylet hub. Punch gripper 81 has an orifice slightly larger than the punch hub. Upon activation of hydraulic (e.g., balloon seal, hydraulic clamping jaws), electromagnetic, or vacuum suction means, the stylet gripper and punch gripper grip the stylet and punch, respectively.

It is preferred that the gripper be provided with a register, which may be a simple "V" shape, against which the stylet or punch hub is positioned for precise positioning.

Obviously, the grippers can be designed and operated similarly, or the grippers can be of different type.

Although there are many ways to construct the punch-changing tissue array instrument, one preferred embodiment will now be described in greater detail. Two punches, a recipient and donor punch, are stored, each in a separate holder on a substrate which also holds the donor and recipient blocks (Fig. 4). Each is provided with a stylet for pushing wax or tissue out of the punch.

Either punch/stylet assembly can be brought under the gripper of the z-axis (Fig. 5) with the same x, y traverse system that is used to move the donor and recipient blocks. The z axis is then used to move the gripper down and grasp the punch that is required for the next operation. When it is necessary to change to a different punch, the empty punch holder 60 is brought under the gripper of the z-axis drive and the z axis drive lowers and releases the punch that is no longer required. The z axis drive

then lifts the empty gripper, the other punch is brought underneath the gripper, and the z-axis drive lowers the gripper to acquire the target punch.

As a punch is acquired, its stylet is connected to the stylet drive in the same operation. The stylet of the active punch may be driven by a simple pneumatic cylinder. The pneumatic cylinder allows precise positioning of the stylet in either the fully up or fully down position, and also allows controlled forces at intermediate positions for tamping the cores, merely by adjusting the air pressure. It would also be within the scope of the invention to use an electromechanical actuator (with force sensor if necessary) instead of the pneumatic cylinder, or to use pneumatic or hydraulic cylinders for positioning the punch.

Preferably, electromechanically driven slides position a pallet in the x and y axes to allow precise positioning of a set of one or more recipient and donor blocks under the punch. All of the motions may be under electronic and computer control by any of many well know means - e.g., limit switches, sensors, position feedback, stepper and/or servo motors and the like.

A typical cycle consists of the desired recipient position being brought under the recipient punch by the x-y drives; the recipient punch being moved by its z drive to penetrate and remove a blank core, creating a pocket for later use; the recipient punch being brought (by the x-y drives) near a waste receptacle (which may be mounted on the same x-y pallet as the blocks) and the recipient stylet being moved to discharge the blank core into the waste receptacle; the recipient punch being returned to its holoder and the donor punch acquired, the desired position of a donor block being brought by the x-y drives under the donor punch; the donor punch being moved by its z drive to penetrate and remove a desired core of tissue; the previously created pocket in one of the recipient blocks being brought by the x-y drives under the donor punch; and finally the donor punch being brought in contact or nearly in contact with the recipient block by its z drive and then its stylet being moved to implant the tissue core in the pocket created in the recipient block. Next, the lateral position is incremented with drives X and or Y to the next position and the cycle is repeated.

It is within the scope of the patent that either the blocks

or the punches can be moved in x, y and z directions relative to the laboratory frame of reference - only relative motion matters in this invention.

It can be seen that there are many combinations and permutations possible with advantages for different applications. The key element that all have in common is the use of at least two separate z drives.

Further, in order to increase the range or capacity of the unattended instrument, it is possible to further provide a magazine containing donor and/or recipient blocks, either fresh or punched, wherein the magazine is operatively associated with said instrument for providing blocks to said instrument and/or receiving blocks from said instrument.

Now that the invention has been described,

I claim:

1. An instrument for constructing arrays of tissue in a recipient block, the instrument comprising:

first and second punch units, each punch unit comprising a punch including a punch hub and a stylet including a stylet hub, means for holding at least one donor block, means for holding at least one recipient block, means for selectively repositioning said recipient block and said donor block relative to said first and second punches.

2. An instrument for constructing arrays of tissue in a recipient block, the instrument comprising:

a platform for holding at least one donor block;
a platform for holding said recipient block;
a first punch unit mounted on a punch arm, said first punch unit comprising a recipient punch and associated stylet;
a second punch unit mounted on a punch arm, said second punch unit comprising a donor punch and associated stylet, said donor punch having an internal diameter greater than said recipient punch; and

means for selectively repositioning said recipient block platform and said donor block platform relative to said first and second punches;

wherein each of said first and second punch units has its own independently operable punch drive, and wherein said first and second punch units are independently moveable along respective first and second punch axis, said punch axis being parallel and spaced apart.

3. The instrument of claim 2, wherein one or more of the platform moving means and the punch moving means are under computer control.

4. The instrument as in claim 2, wherein the donor block holding platform and the recipient block holding platform are different platforms.

5. The instrument as in claim 4, wherein one of said the donor block holding platform and recipient block holding platform

is moveable in at least one of an x and y axis, and wherein the other of said platforms is formed by a turntable rotatable about the z axis.

6. The instrument as in claim 2, wherein the donor block holding platform and the recipient block holding platform are the same platform.

7. An instrument as in claim 6, wherein said donor block holding platform and said recipient block holding platform are driven along x and y axis, and wherein said punches are driven along z axis.

8. An instrument as in claim 7, wherein said donor block holding platform and said recipient block holding platform form a turntable rotatable about the z axis, and wherein either said punches or said platforms are provided with means for movement in least one of the x or y axis.

9. The instrument as in claim 2, wherein the donor punch and recipient punch are independently and simultaneously capable of movement in the z axis.

10. An instrument for constructing arrays of tissue in a recipient block, the instrument comprising:

- first and second punch units, each punch unit comprising a punch including a punch hub and a stylet including a stylet hub,
- means for holding at least one donor block,
- means for holding at least one recipient block,
- gripper means for releasably precisely holding one of said punches at a time,

- means associated with said gripper for moving said stylet hub relative to said punch hub,

- means for precisely moving and positioning said punch hub relative to at least one of said donor and recipient block holders,

- wherein said gripper means is adapted for receiving, moving, and releasing said punches individually.

11. An instrument as in claim 10, wherein said gripper is provided with means for movement in the z axis.

12. An instrument as in claim 10, wherein said donor and recipient block holders are provided with means for movement in the x and y axes for selectively repositioning said recipient block holder and said donor block holder relative to said gripper.

13. An instrument as in claim 10, wherein said donor block and recipient block holders are provided on a turntable rotatable about a z axis.

14. An instrument as in claim 10, wherein one or more of the motions are under computer or manual control via powered drives.

15. An instrument as in claim 10, wherein the donor block holder and the recipient block holder are provided on different platforms.

16. The instrument as in claim 15, wherein one of said the donor block holding platform and recipient block holding platform is moveable in at least one of an x and y axis, and wherein the other of said platforms is formed by a turntable rotatable about the z axis.

17. The instrument as in claim 10, wherein the donor block holder and the recipient block holder are provided on the same platform.

18. An instrument as in claim 2 or 10, further comprising an amount of compliant wadding material provided inside the punch at the tip of the stylet.

19. An instrument as in claim 18, wherein said compliant wadding material is an elastomer.

20. An instrument as in claim 2 or 10, wherein said stylets are driven by an actuator which can exert controlled forces.

21. An instrument as in claim 2 or 10, wherein the stroke length of said stylets can be controlled via said stylet actuators.

22. An instrument as in claim 2 or 10, wherein the stylet actuators are controlled for stroke length via a computer.

23. An instrument as in claim 2 or 10, further comprising a magazine containing blocks, and operatively associated with means for providing blocks to said instrument and/or receiving blocks from said instrument.

INTERNATIONAL SEARCH REPORT

International application No.

PCT/US02/08887

A. CLASSIFICATION OF SUBJECT MATTER

IPC(7) : C12M 1/36

US CL : 422/63; 435/286.2, 286.3, 284.1, 307.1, 307.9

According to International Patent Classification (IPC) or to both national classification and IPC

B. FIELDS SEARCHED

Minimum documentation searched (classification system followed by classification symbols)

U.S. : 422/63; 435/286.2, 286.3, 284.1, 307.1, 307.9

Documentation searched other than minimum documentation to the extent that such documents are included in the fields searched

Electronic data base consulted during the international search (name of data base and, where practicable, search terms used)

C. DOCUMENTS CONSIDERED TO BE RELEVANT

Category *	Citation of document, with indication, where appropriate, of the relevant passages	Relevant to claim No.
A	US 4,684,613 A (BARRERE et al.) 4 August 1987, see abstract.	1-9
A	US 4,979,093 A (LAINE et al.) 18 December 1990, see abstract.	1-23
A	US 6,103,518 A (LEIGHTON) 15 August 2000, see entire document.	1-23

☐ Further documents are listed in the continuation of Box C.☐ See patent family annex.

* Special categories of cited documents:	* later document published after the international filing date or priority date and not in conflict with the application but cited to understand the principle or theory underlying the invention
"A" document defining the general state of the art which is not considered to be of particular relevance	"X" document of particular relevance; the claimed invention cannot be considered novel or cannot be considered to involve an inventive step when the document is taken alone
"E" earlier application or patent published on or after the international filing date	"Y" document of particular relevance; the claimed invention cannot be considered to involve an inventive step when the document is combined with one or more other such documents, such combination being obvious to a person skilled in the art
"L" document which may throw doubts on priority claim(s) or which is cited to establish the publication date of another citation or other special reason (as specified)	"&" document member of the same patent family
"O" document referring to an oral disclosure, use, exhibition or other means	
"P" document published prior to the international filing date but later than the priority date claimed	

Date of the actual completion of the international search

29 May 2002 (29.05.2002)
